The structure of (Fe$^{2+}$)$_2$(Fe$^{3+}$)O$_2$BO$_3$ ludwigite (space group Pbam, $a$=9.462Å, $b$=12.308Å, $c$=3.075Å) is made of zigzag walls of edge-sharing FeO$_6$ octahedra, connected by BO$_3$ triangular groups. It contains two types of 3-leg ladders of Fe cations: ladder 1 with only Fe$^{2+}$ cations and ladder 2 formed by Fe$^{3+}$ cations with one additional electron per rung delocalized at high temperature. This leads to a quite complex physical behavior. Two magnetic ordering transitions are observed at 112K and 70K. Specific heat shows a plateau between ≈100K and 250K, and a change of slope of resistivity is observed close to room temperature. Using single crystal x-ray diffraction, we have shown that it is due to a partial localization of the Fe 3d electrons on ladder 2, accompanied by a superstructure doubling the c-axis.

We report here the investigation of the magnetic ordering, using neutron powder diffraction on I.L.L. D20 between 300K and 10K. Based on the superstructure found with x-rays, both magnetic structures were solved and refined by the Rietveld technique. Between 70K and 110K, only ladder 2 is ordered. The coupling is ferromagnetic in the rungs and antiferromagnetic between them. At 70K, ladder 1 orders as a canted antiferromagnet in the rungs which are ferromagnetically coupled. This also leads to a partial reorientation of the spins of ladder 2. A strong magnetic background increasing from room temperature to 110K could be related to short range correlations in both magnetic sub-units.
